LOCAL FLOW MEASUREMENTS AT THE INLET SPIKE TIP OF A MACH 3.0 SUPersonic CRUISE AIRPLANE

Harold J. Johnson and Earl J. Montoya

NASA Flight Research Center
P. O. Box 273
Edwards, California 93523

The flow field at the left inlet spike tip of a YF-12A airplane was examined using a 26° included angle conical flow sensor to obtain measurements at freestream Mach numbers from 1.0 to 3.0. Local flow angularity, Mach number, impact pressure, and mass flow were determined and compared with freestream values.

Local flow changes occurred at the same time as freestream changes. The local flow usually approached the spike centerline from the upper outboard side because of spike cant and toe-in. Freestream Mach number influenced the local flow angularity; as Mach number increased above 2.2, local angle of attack increased and local sideslip angle decreased.

Local Mach number was generally 2 percent less than freestream Mach number. Impact-pressure ratio and mass flow ratio increased as freestream Mach number increased above 2.2, indicating a beneficial forebody compression effect.

No degradation of the spike tip instrumentation was observed after more than 40 flights in the high-speed thermal environment encountered by the airplane. The sensor is rugged, simple, and sensitive to small flow changes. It can provide accurate inputs necessary to control an inlet.
LOCAL FLOW MEASUREMENTS AT THE INLET SPIKE TIP OF A
MACH 3 SUPERSONIC CRUISE AIRPLANE

Harold J. Johnson and Earl J. Montoya
Flight Research Center

INTRODUCTION

Local flow conditions at the inlet of a supersonic jet aircraft are often considerably
different from free-stream conditions because of forebody effects. In wind-tunnel
inlet–engine testing, test section size limitations often make it impossible to mount the
forebody ahead of the inlet for a model of any significant scale. The forebody often
generates flow gradients which the inlet encounters. Therefore, to compare data from
flight tests with data from wind-tunnel tests conducted without forebodies, local flow
conditions at the inlet during flight tests must be determined as accurately as possible.
Equivalent flight and wind-tunnel test conditions can be obtained by correlating local and
free-stream Mach numbers, angle of attack, and angle of sideslip.

The current joint NASA-U.S. Air Force YF-12A aircraft propulsion system investiga-
tion at Edwards Air Force Base, Calif., requires correlation of flight inlet perform-
ance data with data from wind-tunnel tests of an isolated inlet model without the air-
plane's forebody. To assure that test conditions for the airplane and the wind-tunnel
model were equivalent, a 26° included angle conical pressure probe for obtaining local
flow data was designed and fabricated to replace the YF-12 inlet spike tip.

The feasibility of using conical pressure probes to survey flow fields was demonstra-
ted in references 1 to 5. References 1 to 3 describe small cones which were used to
avoid disturbing the flow field being surveyed in a wind tunnel. These cones had large
orifices relative to the size of the cone, which caused deviations from a theoretical
inviscid sharp cone calibration. The calibration of a larger cone, which was flight-tested
on the X-15 aircraft and is described in reference 5, agreed well with the sharp cone
theory.

Use of the tip of the YF-12 inlet centerbody cone as a local flow sensor made a
special calibration necessary. A full-scale cone, geometrically similar to the flight-
tested cone, was instrumented and tested in the Unitary Plan Wind Tunnel at the NASA
Langley Research Center. These tests covered a range of supersonic Mach numbers at
various incidence angles and at two Reynolds numbers. Details of these calibration
tests are presented in the appendix.

This report presents the characteristics of the local flow at the inlet spike tip of a
YF-12A airplane over a free-stream Mach number range of 1.6 to 3.0 and at Reynolds
numbers from $3.94 \times 10^6$ to $10.18 \times 10^6$ per meter ($1.2 \times 10^6$ to $3.1 \times 10^6$ per foot) for
steady-state and quasi-steady-state flight conditions.
SYMBOLS

Physical quantities in this report are given in the International System of Units (SI) and parenthetically in U.S. Customary Units. The measurements were taken in Customary Units. Factors relating the two systems are given in reference 6.

AIRPLANE

The YF-12A airplane, shown in figure 1, is a prototype interceptor aircraft capable of cruising at speeds in excess of Mach 3 and at altitudes greater than 24,400 meters (80,000 feet). The axisymmetric, mixed-compression inlet has a movable spike as part of the inlet control system. The spike is canted down 5.63° from the wing reference plane and toed in 3.25° from the airplane and nacelle centerline. A three-view drawing of the airplane showing the location of the conical flow sensor at the left inlet spike tip is presented in figure 2.

INSTRUMENTATION

A drawing of the spike tip conical flow sensor and pressure measurement hookup is shown in figure 3. The cone had a nose impact-pressure orifice and four surface static-pressure orifices positioned 90° apart. The hookup technique permitted direct measurement of the differential pressures between the two static-pressure ports in the \( \alpha \)- and \( \beta \)-planes. Absolute-pressure levels were obtained by adding the local static and impact differential pressures to the appropriate reference pressures.

The sensor was designed to meet several requirements. Because it was to replace a spike tip on a YF-12 airplane, the disturbance it caused in the inlet flow field and shock wave system had to be minimal so that inlet performance would not be degraded. It had to be able to withstand high local vibratory g-loads and soak temperatures well in excess of 316° C (600° F).
The sensor was fabricated of stainless steel and had an included angle of 26°, identical to that of the inlet spike. A photograph of the sensor system is shown in figure 4. The sensor portion was attached to a mounting bracket, or web, which held the differential-pressure transducers. These transducers, which were also subjected to the temperatures encountered in high-speed flight, were relatively small, thus allowing close-coupling with the pressure orifices. Tubing lengths of approximately 7.62 meters (25 feet) from the differential-pressure cells to the reference pressure sources were used; 20.3 centimeters (8 inches) of tubing were used from the pressure orifices to the differential-pressure cells. Stainless steel tubing with an outer diameter of 0.477 centimeter (0.188 inch) and a wall thickness of 0.071 centimeter (0.028 inch) was used. Access to the transducers and plumbing system required only the removal of a panel.

Spike tip total and static pressures were measured with differential-pressure cell transducers. Two different absolute reference pressures were applied to the spike tip differential transducers (fig. 3). A high-level pressure was used with the spike tip impact pressure, and a low-level pressure with the static pressures. The reference pressures were measured by high-resolution pressure transducers installed in a controlled temperature environment.

The frequency response of the system was low (1 Hz to 10 Hz); therefore, only quasi-steady-state data were valid. By more careful selection of transducers, hook-up techniques, and tubing lengths, higher frequency response data could have been obtained.

Free-stream Mach number, $M_\infty$, pressure altitude, $h_\infty$, static pressure, $p_\infty$, and impact pressure, $p_i, \infty$, were determined by using the nose-boom-mounted, compensated, pitot-static pressure probe of the airplane. A nose-boom, strut-mounted, hemispherical head, flow-direction sensor was used to obtain free-stream angle of attack, $\alpha_\infty$, and angle of sideslip, $\beta_\infty$. This system is described in reference 7. A photograph of the nose-boom pitot-static probe and hemispherical head sensor is shown in figure 5.

The installed instrumented spike tip and the nose-boom system were connected to a CT-77 pulse code modulation (PCM) system which recorded the data. The PCM data and the time of day were recorded onboard by using a tape recorder and portable time-code generator.

DATA REDUCTION

The YF-12 data reduction system included formatting and digital processing. The formatting process consisted of decommutating, digitizing, and formatting the commutated PCM data into an IBM-compatible format. Through digital processing, the raw data were converted into calibrated engineering units which were listed out for engineering computation. The spike tip pressures were initially converted into three basic non-dimensionalized parameters, $\frac{\Delta p_i}{p_i,l}$, $\frac{\Delta p}{p_i,l}$, and $\frac{p_i,l}{p}$, for use with the wind-tunnel-derived calibration curves shown in figures 6 and 7. The development of these curves
is discussed in the appendix.

The calibration curves were used to obtain local angle of attack, local angle of sideslip, and local Mach number as shown in the flow diagram in figure 8. The procedure was as follows: A first approximation of local Mach number was made by applying the measured value of \( \frac{p_{1,l}}{\rho} \) to the curves of figure 6 and assuming a resolved flow angle of 0°. Using the determined \( M_l \) and figure 7 (0° absolute angle), the value of \( \frac{\Delta p}{p_{1,l}} \deg \) (actually \( \frac{\Delta p_{\beta}}{p_{1,l}} \deg \beta \)) was obtained. Then the measured \( \frac{\Delta p_{\beta}}{p_{1,l}} \) was divided by the \( \frac{\Delta p}{p_{1,l}} \deg \) value to give a first approximation of \( \beta_l \). Next this \( \beta_l \) (absolute angle) was used with \( M_l \) and figure 7 to obtain a new value of \( \frac{\Delta p}{p_{1,l}} \deg \) (actually \( \frac{\Delta p_{\alpha}}{p_{1,l}} \deg \alpha \)), by which the measured value of \( \frac{\Delta p_{\alpha}}{p_{1,l}} \) was divided to obtain the first approximation of \( \alpha_l \). The approximated values of \( \alpha_l \) and \( \beta_l \) were then combined to determine an updated value of \( \Theta \). The value of \( \Theta \) and figure 6 were used to obtain a new \( M_l \). The iteration process was continued (fig. 8) until an acceptably small deviation was obtained, usually after three or four iterations, and the final values of local angle of attack, angle of sideslip, flow angle, and Mach number were then determined.

It was decided to compare the nose-boom and inlet spike \( \alpha \) results relative to the wing reference plane and \( \beta \) results relative to the centerline vertical plane. Because of nose-boom droop and spike cant, corrections had to be applied as shown in figure 9 to obtain \( \alpha_{\infty, wrp}, \beta_{\infty, C} \) (fig. 9(a)) and \( \alpha_{l, wrp}, \beta_{l, C} \) (fig. 9(b)). The sign convention used is also shown in figure 9.

A simplified method of data reduction was used to expedite the data analysis. It was found that the calibration curves in figures 6 and 7 could be approximated by the power series techniques of reference 8 as follows:

\[
M_l = 0.488 + 0.392 \left( \frac{p_{1,l}}{\rho} \right) - 0.0003 \left( \frac{p_{1,l}}{\rho} \right)^2 + \frac{\Theta}{1000} \left[ 4.46 - 4.99 \left( \frac{p_{1,l}}{\rho} \right) + 0.90 \left( \frac{p_{1,l}}{\rho} \right)^2 \right]
\]

\[
\frac{\Delta p}{p_{1,l}} \deg = \frac{1}{1000} \left[ -0.411 + 8.898 M - 1.282 M^2 + (0.2 + C)(\deg \beta \ or \ \alpha) \right]
\]

\( C = 0.25(2.4 - M) \) when \( M < 2.4 \)

\( C = 0 \) when \( M \geq 2.4 \)

The error associated with this approximation was well within the error band of the overall system. This technique could have been applied to an onboard system for in-flight reduction and direct readout.
ACCURACY

The error of the differential-pressure transducers used to record the spike tip pressures was 1 percent of full scale. The error of the reference pressure transducers was ±0.05 percent of full scale. The following table shows the resulting transducer errors:

<table>

**FLIGHT-TEST PROCEDURES**

Data were obtained during stabilized and maneuvering flight. Mach numbers varied from 1.6 to 3.0, and altitudes were as high as 22,850 meters (75,000 feet). Principal test Mach numbers were 2.6, 2.8, and 3.0.

During stabilized runs, the airplane was stabilized for a minimum of 20 seconds at a specified Mach number and altitude. The maneuvering flight conditions consisted of acceleration-climb maneuvers; roller-coaster maneuvers, in which airplane angle of attack was varied in an oscillatory manner; and sideslip tests, which were accomplished by varying the airplane sideslip angle between 2° nose left ($\beta_\infty = 2^\circ$) and 2° nose right ($\beta_\infty = -2^\circ$) and stabilizing briefly at intermediate points. Mach number was held constant during the roller-coaster maneuvers and sideslip tests.

**RESULTS AND DISCUSSION**

The various flight tests served a dual purpose: They made it possible to examine the inlet flow field and to evaluate the performance of various sensors in a high-speed flight environment. By changing the free-stream angle of attack, angle of sideslip, and Mach number, the corresponding changes in local angle of attack, angle of sideslip, and Mach number were obtained and compared with the corresponding free-stream values.

Local Flow Angularity

Figure 10 is a typical time history of a roller-coaster maneuver and a sideslip test. The local conditions are in phase with the free-stream conditions. This indicates similar response characteristics for both the nose-boom and spike tip systems.
Local angles of attack at the inlet spike tip are plotted against free-stream angles of attack for three test Mach numbers in figure 11. It should be noted that free-stream angle of attack is given with respect to the wing reference plane, and local angle of attack is given with respect to both the wing reference plane and the spike centerline. Therefore, it is possible to examine the flow both in terms of change from the free-stream value and in terms of its alinement with the spike centerline. A change in airplane angle of attack caused an essentially equivalent change in local angle of attack, as indicated by the close agreement of the data with the 1 to 1 fairings in the figure.

For each test Mach number, there was a slight upwash at the inlet and the local value of angle of attack was about 0.5° greater than the free-stream value, with respect to the wing reference plane. For a free-stream angle of attack of 4°, a normal condition for Mach numbers from 2.6 to 3.0, the local angle of attack was -0.9°, -1.2°, and -0.8° at free-stream Mach numbers of 2.62, 2.78, and 3.00, respectively. This indicates that the spike was never oriented directly into the local flow in the vertical plane for trimmed flight at these Mach numbers.

The local angles of sideslip at the inlet are plotted against airplane angles of sideslip for approximately the same three test Mach numbers in figure 12. Local angle of sideslip is given with respect to both the airplane centerline and the spike centerline for correlation of local conditions and free-stream conditions. The slope of the fairings at all three Mach numbers is nearly identical and indicates that a change in local angle of sideslip is only about 70 percent as large as the corresponding change in free-stream angle of sideslip.

When the airplane was at a sideslip angle of 0°, the local angle of sideslip with respect to the airplane centerline, $\beta_{l,\text{a}}$, was 0.3°, 0.5°, and 1.2° for free-stream Mach numbers of 2.62, 2.77, and 3.00, respectively. The inlet spikes were turned 3.23° toward the fuselage centerline (fig. 2). As expected, the flow approached the left inlet spike from the outboard side (negative local sideslip). However, an average local sideslip angle of approximately -2.5° was measured for the flight conditions examined. This indicates that the forebody caused an outboard flow, relative to the fuselage vertical centerline.

In addition to the correlation between local and free-stream flow angularity changes, a relationship was observed between local changes in angle of attack and angle of sideslip. During the roller-coaster maneuvers, a 1° increase in local angle of attack was associated with a 0.3° increase in local angle of sideslip. During the sideslip tests, a 1° increase in local angle of sideslip was associated with a 0.37° increase in local angle of attack.

The effect on local flow angularity of increasing free-stream Mach number from 1.6 to 3.0 during an acceleration-climb maneuver is shown in figure 13. Local flow angularity changed little up to a free-stream Mach number of 2.2. Above this Mach number, several significant changes occurred. Local angle of attack decreased from -0.7° at Mach 2.2 to -1.8° at Mach 2.6, after which it remained essentially constant up to Mach 3.0. Local angle of sideslip increased almost linearly from -3.9° at Mach 2.2 to -1.7° at Mach 3.0, indicating that the spike centerline was becoming alined with the local flow field in the horizontal plane as Mach number increased. The steady-state data in the figure agree with the acceleration-climb data.
The results shown in figures 11 to 13 are summarized in figure 14 for Mach numbers from 2.6 to 3.0. These fairings were obtained by plotting local flow angularity as a function of Mach number at several free-stream flow angularity conditions. The curves show a constant value of local angle of attack and a gradually increasing value of local angle of sideslip with increasing Mach number. This type of presentation makes it possible to apply the flight-test results to intermediate Mach numbers, angles of attack, and angles of sideslip for use in future wind-tunnel programs.

Mass Flow, Impact-Pressure, and Mach Number Ratios

On supersonic aircraft, locating inlets in the vehicle's flow field can be advantageous. For example, if beneficial compression effects are measured, a smaller inlet can be used for the required airflow. This smaller inlet may have less drag and weight. The flow field is primarily the result of the aircraft's forebody. Mass flow ratio, \( \frac{m_L}{m_\infty} \), impact-pressure ratio, \( \frac{p_{1,\infty}}{p_{1,L}} \), and Mach number ratio, \( \frac{M_L}{M_\infty} \), are some parameters that are generally used to describe this flow field. These parameters, as measured in flight on the YF-12A airplane, are shown in figure 15. A sketch of the airplane and apparent shock system is included in the figure to show the approximate location of the measurements discussed.

The mass flow ratios were determined by using the local Mach number and impact-pressure ratios shown in figure 15. Mass flow ratio increases from 0.96 at Mach 2.2 to 1.05 at Mach 3.0. A beneficial compression effect (\( \frac{m_L}{m_{\alpha}} > 1.0 \)) is indicated above Mach 2.6 which increases at the higher Mach numbers.

Variations in impact-pressure ratio provide an estimate of the strength and proximity of nearby shock waves. The impact-pressure ratios shown in figure 15 increase from 0.96 at Mach 2.2 to 1.07 at Mach 3.0, indicating the possibility that a forebody shock wave approaches the spike tip as free-stream Mach number increases above Mach 2.2. Below Mach 2.2 the ratio did not change significantly.

The scatter in the local Mach number data of figure 15 was caused by sensor transducer inaccuracy and the sensitivity of the local Mach number to small pressure variations when the calibration curve was applied. In general, local Mach number was 3 percent less than free-stream Mach number, ranging from approximately 1.55 to 2.91 for free-stream Mach numbers from 1.60 to 3.00.

To evaluate the accuracy of the sensor pressure measurements, the pressure coefficient, \( C_p \), of the cone surface static pressures was calculated from the flight-test data and compared in figure 16 with the values obtained with the cone theory of reference 10. The theoretical data are for zero angle of attack, whereas the flight
data are for local angles of attack of less than 2° absolute. The pressure coefficient was calculated by using the following equation:

$$C_p = \frac{\bar{p} - p_l}{q} = \frac{\bar{p} - p_l}{0.7\bar{p} M_l^2}$$

Agreement between the flight data and the theoretical curve was good for local Mach numbers greater than 2.0. Because of the bluntness of the cone (due to the pitot orifice), true conical flow over the spike did not exist at the low Mach numbers as it did for the sharp cone used in the theoretical calculations. This may explain the difference between the data at the lower Mach numbers.

Sensor Evaluation

The conical sensor was used on 40 flights. The system required essentially no maintenance. The transducers performed well in the high temperature and vibration environment of the spike tip.

The YF-12A variable-geometry inlet involves controlled movements of the forward and aft bypass doors and the inlet spike. These movements are scheduled as a function of several parameters, including Mach number, angle of attack, and angle of sideslip, all measured at the nose boom. This type of system cannot be optimized for all flight conditions because of flow differences at the nose boom and at the inlet. These differences make it difficult to calibrate the inlet control system for the greatest efficiency. The efficiency and sensitivity of the system could be enhanced throughout its operating range if a sensor like the conical spike-tip flow sensor used in these tests were installed to obtain the local flow measurements necessary for system operation.

CONCLUDING REMARKS

A 26° included angle conical flow sensor was used to obtain flow measurements at the left inlet spike tip of a YF-12A airplane at Mach numbers from 1.6 to 3.0. Local flow angularity, Mach number, impact pressure, and mass flow were determined from the flight-test data and compared with free-stream values.

Local angle-of-attack and angle-of-sideslip changes occurred at the same time as changes in the free-stream values. A change in free-stream angle of attack caused an equivalent change in local angle of attack, but a change in free-stream angle of sideslip caused a change only approximately 70 percent as large in the local value.

As free-stream Mach number increased above 2.2, the local angle of attack decreased and local angle of sideslip increased. At Mach 3.0, with the airplane in a normal attitude, local angle of attack with respect to the wing reference plane was about 0.5° greater than the free-stream value, and local sideslip angle with respect to the airplane centerline was 1.2°. For the flight conditions examined, the local flow usually approached the spike centerline from the upper outboard side because of spike toe-in and cant.
Local Mach number was generally 3 percent less than free-stream Mach number. No significant change occurred in the impact-pressure ratio or the mass flow ratio as the free-stream Mach number increased from 1.6 to 2.2. As Mach number increased from 2.2 to 3.0, the impact-pressure ratio increased from 0.96 to 1.07 and the mass flow ratio increased from 0.96 to 1.05, indicating the beneficial effect of vehicle compression.

For local Mach numbers greater than 2.0, pressure coefficients determined from flight data agreed well with those calculated using cone theory.

The high speed thermal environment did not adversely affect the sensor system. Use of the instrumented spike tip, which is a rugged, simple system, together with minor improvements in the transducers and frequency response would provide an efficient and accurate sensor for inlet control inputs.

APPENDIX

CONIC WIND-TUNNEL CALIBRATION

TEST APPARATUS

A full-scale instrumented cone, geometrically similar to the cone used in this study (figs. 3 and 4), was calibrated in the Langley Research Center's Unitary Plan Wind Tunnel. The wind tunnel is of the continuous-flow, asymmetric, sliding-block type (ref. 11) and has two test sections. The Mach number range of test section 1 is from 1.47 to 2.86; that of test section 2 is from 2.29 to 4.63.

The cone was mounted to the wind-tunnel sting by means of an adapter section, as shown in figure 17. Pressure lines were run from the cone through the adapter and along the sting to pressure transducers outside the test section. This kept the pressure transducers at room temperature and in a vibration-free environment. The resulting pressure line length was approximately 4.57 meters (15 feet).

Each of the five cone pressures \( p_1, p_2, p_3, p_4, \) and \( p_{1l} \) was measured.

TEST CONDITIONS

Cone pressure data surveys were made at a fixed stagnation temperature of 65.6° C (150° F) for six Mach numbers as follows:

The angle-of-attack range was from \(-4^\circ\) to \(12^\circ\), and angle of sideslip was varied from \(-4^\circ\) to \(6^\circ\) at each Mach number. To check for cone symmetry, the cone was rolled 90° and retested at Mach numbers of 1.5, 2.0, and 3.5.
ACCURACY

Assuming the cone to be correctly fabricated, the accuracy of an instrumented cone is a function of wind-tunnel calibration error and errors associated with the flight instrumentation.

The cone Mach number and angularity calibrations were based on the slopes of curves of $\frac{\Delta p}{p_{1,r}}$ versus angle. This type of wind-tunnel calibration was used because it minimized zero-shift and bias errors caused by the misalignment of the probe and sting deflections due to air loads during the tests. The probe was lined as carefully as possible in the tunnel using a transit and inclinometer. The estimated average sting angle positioning errors are $\pm 0.15^\circ$ for angle of attack and $\pm 0.10^\circ$ for angle of sideslip.

The estimated accuracy of the Mach number cone calibration was based upon the repeatability of pressure data using the calibration in figure 18 and the test section Mach number variation of $\pm 0.015$ for these tests. Over the angular test range the accuracy was estimated to be:

<table>
<thead>
<tr>
<th>M</th>
<th>Estimated error in Mach number calibration</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.5</td>
<td>$\pm 0.017$</td>
</tr>
<tr>
<td>2.0</td>
<td>$\pm 0.020$</td>
</tr>
<tr>
<td>2.4</td>
<td>$\pm 0.023$</td>
</tr>
<tr>
<td>2.8</td>
<td>$\pm 0.028$</td>
</tr>
<tr>
<td>3.2</td>
<td>$\pm 0.031$</td>
</tr>
<tr>
<td>3.5</td>
<td>$\pm 0.034$</td>
</tr>
</tbody>
</table>

The accuracy of flow angle measurement is dependent upon the combined effect of sting-angle-positioning and pressure errors for a given Mach number. The repeatability of the data and the positioning error were used to make the following estimate of the accuracy of the angle-of-attack-angle-of-sideslip calibration:

<table>
<thead>
<tr>
<th>M</th>
<th>Estimated error in $\alpha$-$\beta$ calibration, deg</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.5</td>
<td>$\pm 0.30$</td>
</tr>
<tr>
<td>2.0</td>
<td>$\pm 0.23$</td>
</tr>
<tr>
<td>2.4</td>
<td>$\pm 0.20$</td>
</tr>
<tr>
<td>2.8</td>
<td>$\pm 0.20$</td>
</tr>
<tr>
<td>3.2</td>
<td>$\pm 0.20$</td>
</tr>
<tr>
<td>3.5</td>
<td>$\pm 0.20$</td>
</tr>
</tbody>
</table>
MACH NUMBER CALIBRATION

Conventionally, Mach number cone calibrations have been plotted as \( \frac{\bar{p}}{p_{1t}} \) versus Mach number (refs. 1 and 3 to 5), which resulted in a smooth, nonlinear calibration curve. It was observed in reference 2 that plotting the reciprocal, \( \frac{p_{1t}}{\bar{p}} \), against Mach number resulted in a nearly linear curve. Figure 18 is a plot of \( \frac{p_{1t}}{\bar{p}} \) versus Mach number obtained from wind-tunnel tests with the 26° cone. Results for inclination (\( \alpha \) or \( \beta \)) angles of 0°, -4°, 4°, and 8° are shown. Theoretical results at zero angle of attack for 26° cones (ref. 13) are shown for comparison. The wind-tunnel data and the theoretical results for the 26° cone agree closely over the Mach number range. The effect of increasing inclination angle becomes more pronounced as Mach number increases.

FLOW ANGLE CALIBRATION

Changes in the sensor pressure ratio, \( \frac{p_2 - p_4}{p_{1t}} \), per degree of change in angle of sideslip are shown in figures 19(a) to 19(d) for Mach numbers of 1.5, 2.0, 2.8, and 3.5 for several angles of attack. The slopes of the linear curves increase with Mach number, and at a given Mach number the slopes increase as the absolute value of angle of attack increases.

Figure 20 shows the sensor pressure ratio, \( \frac{p_3 - p_1}{p_{1t}} \), per degree of angle of attack at Mach numbers of 2.0, 2.4, 2.8, and 3.5 for zero angle of sideslip. Results from tests performed at Mach 2.0 and Mach 3.5 at different Reynolds numbers are also shown. No significant Reynolds number effects are apparent. The slope of \( \frac{p_3 - p_1}{p_{1t}} \) also increased with Mach number.

The symmetry of the cone was checked by rotating the cone 90° and repeating the tests at Mach numbers of 2.0 and 3.5. The results of the rotated and normal cone tests are compared in figure 21. Good agreement of the data from these tests was obtained at both Mach numbers, which indicates that the cone was symmetrically machined and installed in the tunnel.

The slopes of the linear cone test data typified by figures 19 to 21 were measured at each Mach number. These slopes were plotted against free-stream Mach number to obtain the calibration shown in figure 22. At the lower Mach numbers (near 1.5) small changes in the cone surface static pressures could result in significant angular variation. At the higher Mach numbers, the angularity calibration is less sensitive to variations in Mach number. The spike tip pressure relationships at the higher Mach numbers gave an estimated error in the \( \alpha-\beta \) calibration of ±0.20°.
